Transportation for Sustainable Communities: A cost and impact comparison between alternative transportation modes.

Professor Patrick M. Condon, University of British Columbia
Kari Dow, University of British Columbia.

ABSTRACT
In this paper, the authors ask: what is the optimal relationship between sustainable community design and transit? This seemingly straightforward question is very rarely asked in a literature dominated by work that typically focuses on one or the other element of sustainable community design or assumes a technical orientation to transportation questions without regard to community design and community context. What is lacking is a holistic approach. In this modest attempt we ask “what transit system is optimal” against three well accepted sustainability criteria: long term cost, greenhouse gas reduction, and compatibility with complete community objectives. Our results strongly suggest that modern, at-grade tram technology should be the mainstay of any sustainable community design. Tram was found to be one of the most affordable modes in terms of long term environmental and economic cost; it was consistently associated with urban form that boasts the lowest total per capita greenhouse emissions; and it is highly compatible with complete community objectives. Our data is primarily from accepted secondary sources, with the exception of data from the Toronto Transit Authority, which is primary. Our unique contribution to the discourse is in assembling this information in such a way that more broadly sustainable choices begin to emerge.
Introduction

What is the optimal relationship between land use and transit, and what transit mode would best support this optimum state. On this there is no agreement – neither in the Vancouver region, the major focus of this paper, nor in the rest of North America. Most North American transportation planners argue for transit services optimized to serve the long, high speed commute trip. Given that transit resources are limited, this is usually at the expense of local service. In the Vancouver region this position has held sway, with billions of dollars spent to expand the automated high speed, grade separated “Skytrain” system, and billions more on the table for future expansions (Translink 2008a; Translink 2008b) [Figure 1]. Other transportation planners, seemingly fewer in number, argue in favor of systems that provide much better local service, but have the slower traveling speeds more suited to shorter trips (Black et al. 2002; Dittmar & Ohland 2004; Farr 2007). Very few metropolitan transit agencies take this position. The City of Portland Oregon, which invested in its own streetcar system, is one of the very few (Dom & Kelly, 2007) [Figure 2]. Thus, the first question examined in this research is this: Which of these two positions represents the more sustainable option? In this paper we attempt to clarify this question, if not definitively answer it. It is the opinion of the authors that unless and until we can clarify exactly what transit is for, and how it fits into broader concepts for sustainable urban regions, we will always be talking at cross-purposes.

Our second question is what mode has the lowest ecological impact? It is no longer morally defensible to choose transportation technologies without considering our national responsibility to reduce greenhouse gases (GHG) by 80% by 2050. Legislation now exists that requires municipalities and regions to arrange land uses and transportation systems in a manner that reduces our greenhouse gas (GHG) emissions (California’s Assembly Bill 32: Global Warming Solutions Act, Washington’s H.R. 2454, "The American Clean Energy and Security Act," Oregon’s H.B. 2186A, and British Columbia’s Greenhouse Gas Reduction Targets Act). The use of transit, which was heretofore considered solely from the perspective of reducing auto dependence and providing transportation equity to the disadvantaged, now has a broader mandate. Transit must help governments meet their GHG targets. For this reason we examine the carbon emissions associated with a variety of transit technologies, while also comparing them against private automobiles. What good does it do us if everyone rides the bus if that bus still produces more greenhouse gas per passenger mile than the car it replaces?

Our third question is what technology is more cost effective over the long term, when all costs are considered? Investment decisions made this decade will determine land use and transportation patterns that will last for the next hundred. How can we choose the system that helps create the kind of cost and resource efficient region that the future demands?

Sustainability Principles

In keeping with our methodological choice (i.e. to assess this question broadly against sustainability goals rather than narrowly focusing on transportation per se) we organize this information against three fairly well accepted sustainability principles. First, whatever the mode,
we are assuming that shorter trips are better than longer trips. Transporting people requires energy, and energy, even from ‘green’ sources, has its costs. The optimal relationship between transportation and land use is one that ultimately supports and extends the walk and bike trip. Complete communities require shorter trip distances. Thus we ask what is the arrangement of transit and land uses that leads to the lowest average daily per capita demand for vehicle travel of any kind?

Secondly, we know that low carbon is better than high carbon. Therefore, what transportation mode has the least carbon emissions per trip? How does the energy source factor in to this carbon calculation? Here in British Columbia most of the electricity used to power the Vancouver Region’s Skytrain system and trolley busses comes from hydroelectric sources. Thus these trips, discounting externalities, are essentially carbon zero. But if the power driving these vehicles came not from hydroelectric sources but from fossil fuels, what would this mean for our carbon calculations?

Finally, we should choose what is most affordable over the long term. Long term capital, operating, maintenance and replacement costs need to be considered and evaluated to find the most efficient transportation mode. The public purse is only so full, and money spent on expensive systems usually translates into other resource demands on the planet that also must be reduced.

We thus frame this analysis against these three sustainability principles, principles that we feel are unassailable. We do not, however, attempt to employ this framework to definitively answer these three main questions. Our work is too preliminary to do so. Furthermore it is unlikely that any work however extensive could definitively prove out an unassailable conclusion to such broadly framed questions. These questions, and other sustainability questions like them, have far too many interacting variables to lend themselves to classical proofs. What we CAN accomplish is to suggest how necessarily complex questions may be more intelligently framed than is currently the case, and framed against sustainability goals, the achievement of which the survival of the planet now literally depends.

Transportation Options Compared

The following transportation modes are compared throughout the report:

- Modern Tram: based on Siemens’ Combino Plus featuring articulated, low floor, rail vehicles with regenerative braking technology, operating in existing street right of ways [Figure 3].
- Trolleybus: based on the Vancouver region’s New Flyer electric rubber-wheeled trolley bus featuring low floor vehicles with regenerative braking technology [Figure 4].
- Skytrain: automated, mostly elevated, rapid rail transit Mark I and Mark II vehicles in service in Vancouver, BC [Figure 5].
- LRT: SD-400 and SD-460 90’ single articulated vehicles. Light Rail Transit differs from trams in that it generally operates in separate rights-of-way with less frequent stops and raised boarding platforms.
- Articulated Diesel Bus: 60’ vehicles used in high-capacity, high-frequency BRT express routes (operates in traffic, no signal control) [Figure 6].
- Diesel Bus (40’): 1998 40’ Gillig Phantom vehicles in service in St. Louis.
- 2007 Toyota Prius: hybrid electric mid-sized car that won Green Engine of the Year 2008 from International Engine of the Year Awards [Figure 7].
- 2007 Ford Explorer: mid sized sport utility vehicle (SUV) popular in North America [Figure 8].

**Principle 1: Shorter trips are better than longer trips**

*What is the best mode for short trips that act as an extension of the walk trip?*

If shorter vehicle trips are the goal, what is the best transit option? Most experts agree that for short trips options to the car include the walk, the bike, the bus, or the tram. Certainly the walk and the bike trip have the least impact on the planet and the lowest cost. But to extend the walk trip the bus and the tram are the logical next mode shift. Traditional “streetcar neighbourhoods” of the type that characterize most North American urban districts built prior to 1930, generally encourage shorter trip length due to their close proximity of activities, their fine-grained mix of land uses, and their grid-like street networks.

This hypothesis is born out by data that shows that North American districts still served by streetcar, and their kindred rubber tired cousins the trolley bus, exhibit shorter average trip lengths than other modes (2.5 and 1.6 miles respectively). On the other hand, the average daily trip length in a personal automobile in the United States is 9.9 miles (Buehler, Pucher and Kunert 2009). Other trip length averages across the United States were found to be 3.9 miles for local bus, 5.0 miles for BRT, and 4.6 miles for LRT. These values are represented in Figure 9 [Figure 9].

**Principle 2: Low carbon is better than high carbon**

*What transportation mode is most energy efficient?*

While both busses and trams are an effective way to extend the walk trip, trams are inherently more energy efficient than buses (Strickland, 2008), lose less energy to frictional resistance, and generally have higher passenger capacities [Figure 10].

Trams also more frequently capitalize on regenerative braking technology, which allows them to convert the kinetic energy of the vehicle in motion to electrical energy when it brakes. This energy is either returned to the overhead wires for use by other vehicles or used to power auxiliary equipment such as onboard heating/cooling systems (ExecDigital 2007). Modern trams like Siemens’ Combino Plus, are able to recover 30 percent of the energy used to power the vehicle through this process (Blumenthal et al. 1998). A study of Combino’s performance in the field found that at slower average speeds (19 km/hr) energy recovery from regenerative braking was more than 42 percent (Blumenthal et al. 1998).

When converting energy efficiency into kilowatt hours we found that the energy efficiency of a modern tram is approximately 0.11 kWh per passenger-mile, LRT is 0.13, Skytrain is 0.30, trolleybus is 0.36, articulated diesel bus is 0.56, the Toyota Prius is 0.64, the 40’ diesel bus is 0.75 and the Ford Explorer is 1.42 kWh per passenger-mile (all figures for typical capacity).
What transportation mode has the lowest carbon emissions per passenger-mile?

Carbon emissions by different modes of transportation are primarily influenced by the type of fuel the vehicle uses and the efficiency of the motor used to process it. In this study we look at regular gasoline, diesel and electricity as the primary sources of energy in the transportation sector. Because electricity can be generated in a number of different ways we have included electricity generated from a coal plant, a natural gas plant and a hydro-electric plant to highlight the range of potential carbon emissions from this sector.

Table 1. Carbon Equivalent Emissions by Energy Source

</tr>
</tbody>
</table>

Applying these emissions to our transportation modes based on their source of energy we can calculate their carbon emissions per passenger-mile. Even when using electricity generated from a coal burning power plant (Figure 14), the carbon emissions for electric powered vehicles is far lower than vehicles using internal combustion engines.

To better understand why electrically powered vehicles are so much cleaner than gasoline or diesel powered vehicles (even when carbon emissions produced by gasoline, diesel and coal differ by only 56 grams of CO₂ emissions/ kWh) we must look at the energy efficiency of the electric motor versus the internal combustion motor. According to Strickland (2008) internal combustion engines typically convert, at best, 1/3 of their energy into useful work while electric motors generally have energy efficiencies of 80-90 percent. This means that electrically powered vehicles perform significantly better from the perspective of carbon mitigation and energy efficiency in comparison with the relatively inefficient internal combustion engine.

Although we have focused here primarily on the carbon emissions from the actual movement of vehicles, there are also significant carbon emissions associated with vehicle manufacturing and maintenance, infrastructure construction and fuel production. Quantifying the full lifecycle carbon consequences of each mode is far beyond the scope of this article however, recent research by Chester (2008) provides some insight into this question. He found that life-cycle greenhouse gas emissions are 47-65 percent larger than vehicle operation emissions for automobiles, 43 percent for buses, and 39-150 percent for rail (modern trams, with their minimal
construction requirements, would be on the lower end of this range while Skytrain would be on the higher end) (Chester 2008). The GHG consequences of all the concrete used in the construction of elevated or buried subway systems such as Skytrain boosts the GHG consequences of this mode significantly making it likely that the investment in this infrastructure will return far less GHG advantage than is normally attributed to this transportation mode.

[Figure 15]

**Principle 3: Choose what is most affordable over the long term.**

*Given the long term capital, operating, maintenance and replacement costs what mode is the most efficient/cheapest?*

To make a sound comparison of the long term aggregate costs per passenger-mile associated with each transportation mode we incorporated capital costs associated with acquiring the vehicles and constructing the infrastructure necessary to support them. The total cost was then amortized over the expected life of the system and this annualized cost was divided by the actual annual passenger-miles recorded by the transit authority.

The capital costs for transportation modes such as streetcar, LRT and Skytrain are relatively easy to determine because the large initial investment to build the transportation infrastructure (tunnels and elevated tracks, vehicles, stations etc.) is generally tied directly to the project. However, many costs associated with personal automobile, local bus service, and to a lesser extent at-grade trams, BRT and trolley bus, are more difficult to determine because they operate on existing roadways, the construction and maintenance of which are not included in most cost calculations for these modes. For this reason we have included external costs that begin to place a value on the land and resources dedicated to automobile infrastructure. Because the transportation sector is far from agreement on which external costs should be included in valuations of this kind we have provided a high (full) and a low (basic) estimation of external costs as listed in the caption for Figure 16. [Figure 16]

Modes such as LRT and Skytrain have very low external costs because the infrastructure for these types of projects generally have to be built from scratch so the costs are already included in their higher initial capital costs. The capital and full external costs per passenger-mile for each transportation mode are shown in Figure 17. [Figure 17]

Next, on-going operation and maintenance expenses were calculated. These costs are shown in Figure 18. [Figure 18]

In Figure 19 the capital costs, full external costs and operating costs were totaled. Figure 20 shows the same calculations but with basic external costs. Both of these figures show the cost that is currently spent on energy for each mode as well as the future increase in energy costs that can be expected as non-renewable fuels such as oil become more scarce. Using full external costs, the Toyota Prius scores best per passenger-mile with a total cost of $1.09 followed by modern tram at $1.23. Even with negligible energy costs, Skytrain is by far the most expensive at $2.66 per passenger-mile. [Figure 19 and 20]
The results shown in Figure 19 and 20 show the cost of moving one person one mile. This kind of calculation tends to favour modes of transportation that typically travel longer distances. But since shorter trips are, in the context of this argument, more sustainable, we are also interested in, or perhaps more interested in, what is the cost per average trip. Low average trip distance is a marker for a more sustainable district, as it indicates that the relationship between mode and land use has been optimized. Conversely, low costs per mile gain us nothing if the relationship between mode and land use is such that all trips are unnecessarily long.

The calculated costs per trip are shown in Figure 21. In this scenario, the transportation modes encouraging land use that support shorter trips (trolleybus and modern tram) are significantly more cost effective than modes that facilitate more spread out land use patterns (ie. modes designed for high speed, long distance trips). [Figure 21]

**Optimal Relationship Between Land Use and Transportation**

Based on the three sustainability criteria, reducing trip length, greenhouse gas reduction, and lifecycle cost, trams represent the best transportation investment. But how does this relate to urban form? We begin this investigation by exploring the ideal transect arrangement for sustainable communities.

The field of sustainable urban planning can be grouped into two general schools of thought. One favors concentrating growth in high density nodes served by high speed transit. The other favors a smaller scale approach that sees growth redistributed along fine-grained frequent transit networks that have slower travelling speeds but are more accessible to a larger portion of the urbanized land area.

In recent decades, most urban areas in North America have been transformed by this first approach to city planning. It has resulted in cities that are characterized by high density urban centres (> 50 du/acre) surrounded by lower density suburbs (often less than 5-6 du/acre). The range from high to low density is extreme. These cities can be described as ‘pointy,’ both in terms of building height as well as housing and job density.

The second approach was the approach taken by many cities in North America during the first half of the 20th century. It also continues to be common in many European cities and some parts of Australia, South America and Asia. This approach tends to result in medium-low to medium-high densities (15 – 40 du/acre) across the urbanized area. In these ‘flat’ cities there is often little to no change in building height as you travel from the urban core to the surrounding suburbs. Job concentration may still be somewhat higher in the core, but in contrast to pointy cities, housing, jobs, commercial services and amenities are distributed much more evenly throughout the urban landscape. Figure 22 shows the City of Oslo, where building heights are remarkably consistent throughout the urban fabric.

Table 2 shows two metropolitan areas that exhibit classic ‘flat’ and ‘pointy’ urban transects. Vancouver is slightly atypical in the North American context due to it’s multiple City Centres and historic streetcar neighbourhoods and therefore falls somewhere in between the ‘flat’ and
‘pointy’ categories. These three metro areas were chosen because their urban form varies significantly but their geographic, political and economic characteristics are very similar. All three are constrained by steep topography and water, have mild climates and perhaps most importantly, all three supply much of their energy demand with hydroelectric power. Despite these similarities, the annual per capita GHG emissions vary significantly between the three cities. Oslo, with an average daily trip length of 8.8km has annual GHG emissions of 4.3 tCO2 per person. Vancouver has an average daily trip length of 9.3km and 5.7 tCO2 per person per year while Seattle has an average daily trip length of 28.8km and annual GHG emissions of 13.7 tCO2 per year.

Conclusion

Although more research into the optimal relationship between land use and transportation needs to be conducted before even the most tentative conclusions can be drawn, it is enough to begin a dialogue that takes as it’s point of departure, a more holistic approach to transportation planning; one that broadens the parameters of how we evaluate our various options.

In terms of our three sustainability criteria, at-grade tram technology represents the best investment. This investment only makes sense if a region and it’s officials are committed to a long term strategy of balancing jobs and housing, and to reducing the daily per capita demand for transportation of all kinds. If most trips in a region are short, then the rationale for investment in trams is overwhelming. If all trips are long then the rationale for the very expensive heavy rail subway or elevated systems may still hold sway. Currently the Vancouver region is at a tipping point between the two. Decisions made now about which mode to invest in could precipitate very different land use consequences, consequences lasting for decades. These arguments apply to every North American metropolitan area. All are struggling with these same questions. This paper does not provide a definitive answer to which path to take, but attempts to illuminate the significance of the choice. We only have till 2050 to radically reduce our carbon and resource demands on the planet, therefore investments made in this decade must be intelligent and set in place the land use and transportation armature that is compatible with that challenging goal. This generation of citizens and decision makers will determine, by its choices, what our urban regions will look like in 20, 50, 100 years. Hopefully they will be much more sustainable than they are now. If they are not, we simply wont reach our GHG reduction goals. How we spend the billions proposed for investment in transit this decade will likely be decisive.
